

Keratoacanthoma is a benign, self-healing skin tumor that typically presents as a solitary, dome-shaped, crusted nodule. It is characterized by a central keratin-filled crater and a raised, erythematous border. The lesion is usually found on sun-exposed areas of the skin, such as the face, arms, and hands. Histologically, it shows a well-circumscribed, nodular growth of keratinocytes with a central keratin-filled crater. The tumor is composed of a central keratin-filled crater surrounded by a thick, multi-layered keratin wall. The underlying dermis shows a dense infiltrate of inflammatory cells, including neutrophils and lymphocytes. The tumor is typically found in the dermis and may extend into the subcutaneous tissue. It is a benign lesion and usually resolves spontaneously within 6-8 weeks. Treatment options include surgical excision, cryotherapy, and topical retinoids. The use of interferon has been reported in some cases, but its efficacy is not well established.
